# Data Structures Chapter 1

- 1. Recursion
  - Recursion
  - Mergesort
- 2. Performance Analysis
- 3. Asymptotic Analysis

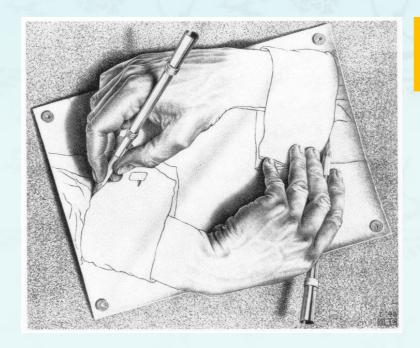

#### Recursion

See Recursion

#### Recursion

- See Recursion
- Recursion is when a function calls itself
- Recursion simplifies program structure at a cost of function calls
- Recursion vs. Leap of faith

recursion is when a function calls itself

#### **Example 1: BunnyEars**

- What is the output of the function bunnyEars()?
- What is the output of the function main()?
- How many times does two returns execute, respectively?

```
int bunnyEars(int n) {
   cout << n << endl;
   if (n > 0)
      return bunnyEars(n - 1) + 2;
   return 0;
}

int main() {
   cout << bunnyEars(4) << endl;
}</pre>
```

```
bunnyEars(4)
    cout << 4
         bunnyEars(3)
         cout << 3
4
5
              bunnyEars(2)
              cout << 2
6
                    bunnyEars(1)
8
                    cout << 1
9
                         bunnyEars(0)
16
                         cout << 0
                                          return 0
```

system stack

#### **Example 1: BunnyEars**

- What is the output of the function bunnyEars()?
- What is the output of the function main()?
- How many times does two returns execute, respectively?

```
int bunnyEars(int n) {
   cout << n << endl;
   if (n > 0)
      return bunnyEars(n - 1) + 2;
   return 0;
}

int main() {
   cout << bunnyEars(4) << endl;
}</pre>
```

```
bunnyEars(4)
    cout << 4
         bunnyEars(3)
         cout << 3
4
5
              bunnyEars(2)
              cout << 2
6
                    bunnyEars(1)
8
                    cout << 1
9
                         bunnyEars(0)
16
                         cout << 0
                                           return 0
   f(n=1)
   f(n=2)
   f(n=3)
             system
   f(n=4)
             stack
```

#### **Example 1: BunnyEars**

- What is the output of the function bunnyEars()?
- What is the output of the function main()?
- How many times does two returns execute, respectively?

```
int bunnyEars(int n) {
   cout << n << endl;
   if (n > 0)
      return bunnyEars(n - 1) + 2;
   return 0;
}

int main() {
   cout << bunnyEars(4) << endl;
}</pre>
```

```
bunnyEars(4)
    cout << 4
                                          return f(3) + 2
         bunnyEars(3)
         cout << 3
                                          return f(2) + 2
4
5
              bunnyEars(2)
                                          return f(1) + 2
              cout << 2
6
7
                   bunnyEars(1)
                   cout << 1
                                          return f(0) + 2
8
9
                         bunnyEars(0)
16
                         cout << 0
                                          return 0
```

system stack

# **Example 2: FunnyEars**

We have bunnies and funnies standing in a line, numbered 1, 2, ... The odd bunnies (1, 3, ..) have the normal 2 ears. The even funnies (2, 4, ..) we'll say have 3 ears, because they each have a raised foot. Recursively return the number of "ears" in the bunny and funny line 1, 2, ... n (without loops or multiplication).

#### **Expected results:**

```
funnyEars(0) \rightarrow 0
funnyEars(1) \rightarrow 2
funnyEars(2) \rightarrow 5
funnyEars(3) \rightarrow 7
funnyEars(4) \rightarrow 10
funnyEars(10) \rightarrow 25
funnyEars(11) \rightarrow 27
```

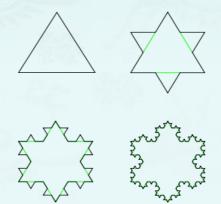

```
int funnyEars(int n) {
   if (n <= 0) return 0;
   if (n % 2 == 0)
       return _____;

return _____;
}</pre>
```

```
int main() {
    int funnies[] = {0, 1, 2, 3, 4, 10, 11};
    for (auto n: funnies)
        cout << funnyEars(n) << endl;
}</pre>
```

#### Recursion

- Recursion is a method where the solution to a problem depends on solutions to smaller instances of the same problem (as opposed to iteration).
- Recursive algorithm is expressed in terms of
  - base case(s) for which the solution can be stated non-recursively,
  - 2. recursive case(s) for which the solution can be expressed in terms of a smaller version of itself.

Four stages in the construction of a **Koch snowflake**. The stages are obtained via a recursive definition.

# **Example 3: Factorial**

$$fact(n) = \begin{cases} 1 & \text{if } n = 0\\ n \cdot fact(n-1) & \text{if } n > 0 \end{cases}$$

#### factorial(n)

function factorial

**input**: integer n such that  $n \ge 0$ 

output:  $[n \times (n-1) \times (n-2) \times ... \times 1]$ 

- 1. if *n* is 0, **return** 1
- 2. otherwise, **return** [ $n \times factorial(n-1)$ ]

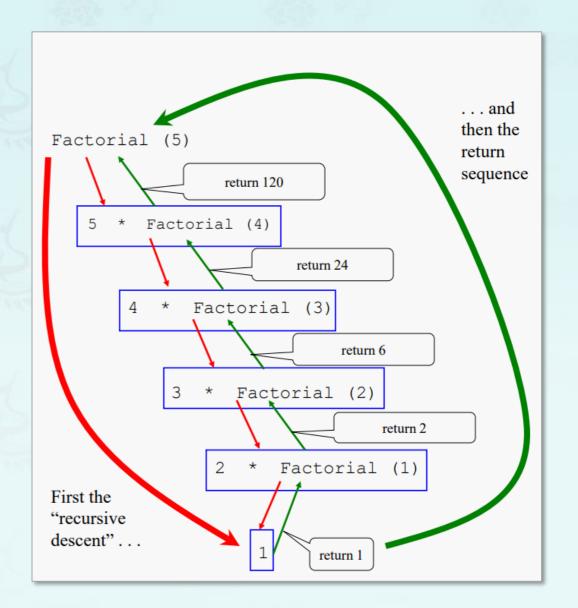

end factorial

# factorial (n = 4) $f_4 = 4 * f_3$ $= 4 * (3 * f_2)$ $= 4 * (3 * (2 * f_1))$ $= 4 * (3 * (2 * (1 * f_0)))$ = 4 \* (3 \* (2 \* (1 \* 1))) = 4 \* (3 \* (2 \* 1)) = 4 \* (3 \* 2) = 4 \* 6 = 24

# **Example 3: Factorial**

$$fact(n) = \begin{cases} 1 & \text{if } n = 0\\ n \cdot fact(n-1) & \text{if } n > 0 \end{cases}$$

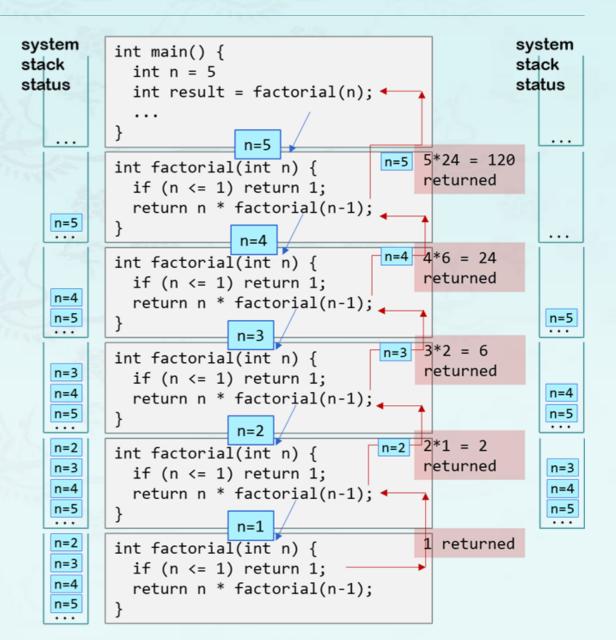

```
int factorial(int n) {
   if (n <= 1) return 1;
   return n * factorial(n - 1);
}</pre>
```

# **Example 3: Factorial**

```
fact(n) = \begin{cases} 1 & \text{if } n = 0\\ n \cdot fact(n-1) & \text{if } n > 0 \end{cases}
```

```
int factorial(int n) {
   if (n <= 1) return 1;
   return n * factorial(n - 1);
}</pre>
```

Predict the output of the following code.

```
#include <iostream>
using namespace std;

void foo(int n) {
    if (n < 1) return;
    cout << n << " ";
    foo(n - 1);
    cout << n << " ";
    return;
}

int main() {
    int x = 3
    foo(x);
}</pre>
```

```
void foo(n=3)
  if (n < 1) return;
  cout << n << " ";
  foo(2);
  cout << n << " ";
  return;</pre>
```

• When foo(3) is called in main(), memory is allocated to **foo(3)** and a local variable **n** is initialized to **3**, while main() is pushed on the stack.

Predict the output of the following code.

```
#include <iostream>
using namespace std;

void foo(int n) {
    if (n < 1) return;
    cout << n << " ";
    foo(n - 1);
    cout << n << " ";
    return;
}

int main() {
    int x = 3
    foo(x);
}</pre>
```

```
void foo(n=3)
  if (n < 1) return;
  cout << n << " ";
                         foo(3) calls foo(2)
  foo(2);
  cout << n << " ";
                        void foo(n=2)
  return;
                          if (n < 1) return;
                          cout << n << " ";
                                                 foo(2) calls foo(1)
                          foo(1);
                          cout << n << " ";
                                                void foo(n=1)
                          return;
                                                  if (n < 1) return;</pre>
                                                  cout << n << " ";
                                                                         foo(1) calls foo(0)
                                                  foo(0);
                                                  cout << n << " ";
                                                                        void foo(n=0)
                                                  return;
                                                                         if (n < 1) return;
```

- When foo(3) is called in main(), memory is allocated to foo(3) and a local variable n is initialized to 3, while main() is pushed on the stack.
- It prints '3'. foo(2) is called and memory is allocated to foo(2) and a local variable n is initialized to 2, while foo(3) is pushed on the stack.
- Similarly, foo(2) calls foo(1) and foo(1) calls foo(0).

Predict the output of the following code.

```
#include <iostream>
using namespace std;

void foo(int n) {
    if (n < 1) return;
    cout << n << " ";
    foo(n - 1);
    cout << n << " ";
    return;
}

int main() {
    int x = 3
    foo(x);
}</pre>
```

```
void foo(n=3)
  if (n < 1) return;
  cout << n << " ";
                         foo(3) calls foo(2)
  foo(2);
  cout << n << " ";
                        void foo(n=2)
  return;
                          if (n < 1) return;
                          cout << n << " ";
                                                 foo(2) calls foo(1)
                          foo(1);
                          cout << n <<
                                                void foo(n=1)
                          return;
                                                 if (n < 1) return;</pre>
                                                  cout << n << " ";
                                                                        foo(1) calls foo(0)
                                                  foo(0);
                                                 cout << n << " ";
                                                                       void foo(n=0)
                                                  return;
                                                                         if (n < 1) return;
                                             returns foo(n=1)
```

- When foo(3) is called in main(), memory is allocated to foo(3) and a local variable n is initialized to 3, while main() is pushed on the stack.
- It prints '3'. foo(2) is called and memory is allocated to foo(2) and a local variable n is initialized to 2, while foo(3) is pushed on the stack.
- Similarly, foo(2) calls foo(1) and foo(1) calls foo(0). foo(0) goes to if statement and it returns to foo(1).

Predict the output of the following code.

```
#include <iostream>
                                           void foo(n=3)
                                             if (n < 1) return;
using namespace std;
                                             cout << n << " ";
                                                                  foo(3) calls foo(2)
                                             foo(2);
void foo(int n) {
                                             cout << n << " ";
                                                                 void foo(n=2)
    if (n < 1) return;
                                             return;
                                                                   if (n < 1) return;
    cout << n << " ";
                                                                   cout << n << " ";
                                                                                         foo(2) calls foo(1)
    foo(n - 1);
                                                                   foo(1);
                                                                   cout << n <<
    cout << n << " ";
                                                                                       void foo(n=1)
                                                                   return;
                                                                                         if (n < 1) return;
    return;
                                                                                         cout << n << " ";
                                                                                                              foo(1) calls foo(0)
                                                                                         foo(0);
                                           returns foo(n=3)
                                                                                         cout << n << " ";
                                                                                                             void foo(n=0)
int main() {
                                                                                         return;
                                                                                                              if (n < 1) return;
  int x = 3
                                                               returns foo(n=2)
  foo(x);
                                                                                     returns foo(n=1)
```

- When foo(3) is called in main(), memory is allocated to foo(3) and a local variable n is initialized to 3, while main() is pushed on the stack.
- It prints '3'. foo(2) is called and memory is allocated to foo(2) and a local variable n is initialized to 2, while foo(3) is pushed on the stack.
- Similarly, foo(2) calls foo(1) and foo(1) calls foo(0). foo(0) goes to if statement and it returns to foo(1).
- Foo(1) pops from the stack and the remaining statements of foo(1) are executed. Then it returns to foo(2) and so on.
- In the output, values from 3 to 1 are printed and then 1 to 3 are printed.

#### Reminder

 Recursion is a method where the solution to a problem depends on solutions to smaller instances of the same problem (as opposed to iteration).

- Binary search is an efficient algorithm for finding an item from a sorted list of items.
  - It works by repeatedly dividing in half the portion of the list that could contain the item,
  - until you've narrowed down the possible locations to just one.

					4					
key=23	2	5	8	9	16	23	31	56	62	71

 For instance, we want to search "23" from the array. If we find it, we return its array index; otherwise, -1 or something else.

```
0 1 2 3 4 lo=5 hi=6 7 8 9
2 5 8 9 16 23 31 56 62 71
```

 For instance, we want to search "23" from the array. If we find it, we return its array index; otherwise, -1 or something else.

```
key=mi
23=23
```

```
0 1 2 3 4 lo=5 hi=6 7 8 9
2 5 8 9 16 23 31 56 62 71
```

- How many times is the binarySearch() called in terms of n?
- In one call to binarySearch(), we eliminate at least half the elements from consideration. Hence, it takes  $log_2 n$  (the base 2 logarithm of n) binarySearch() calls to compare down the possibilities to one. Therefore binarySearch takes time proportional to  $log_2 n$ .

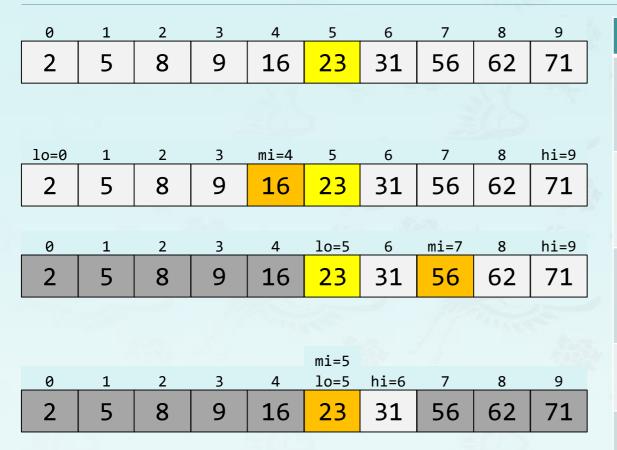

```
int binarySearch(int list[], int key, int lo, int hi) {
  if (lo > hi) return -1;

mi = (lo + hi)/2;
  if (key == list[mi]) return mi;  // base case
  if (key < list[mi])  // recursive case
   return binarySearch(list, key, lo, mi - 1);
  else
   return binarySearch(list, key, mi + 1, hi);
}</pre>
```

- Given the numbers 1 to 100, what is the minimum number of guesses needed to find a specific number if you are given the hint 'higher' or 'lower' for each guess you make?
  - Since the numbers are sequential (or sorted), we can use binary search.
  - Look at the middle element: if it's after than the number we're looking for, search the first half. If it's before the number we're looking for, look at the second half.
  - Each check cuts the size of the list numbers in half; how many times can we do this?
  - If we think backwards, in terms of doubling the list, we'll need n doublings to generate a list of length  $2^n = 100$ . What is the value of n?
  - Since  $2^6 = 64$  and  $2^7 = 128$  (or  $log_2 64 = 6$ ,  $log_2 128 = 7$ ), n = 6.x Therefore n = 7 guesses will be enough.

- Given the numbers 1 to 1000, what is the minimum number of guesses needed to find a specific number if you are given the hint 'higher' or 'lower' for each guess you make?
  - For an array whose length is 1000, the closest lower power of 2 is 512, which is 2^9.
  - We can thus estimate that  $log_21000$  is a number greater than 9 and less than 10, or use a calculator to see that its about 9.97. Adding one to that yields about 10.97.
  - In the case of a decimal number, we round down to find the actual number of guesses.
  - Therefore, for a 1000-element array, binary search would require at most 10 guesses.

Most operating systems give a program enough stack space for a few thousand stack frames. If you use a recursive procedure to walk through a million-node list, the program will try to create a million stack frames, and **the stack will run out of space**. The result is a run-time error.

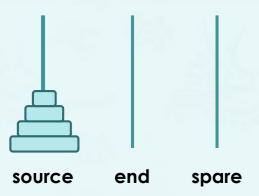

• Given three pegs, one with a set of N disks of increasing size, determine the minimum (optimal) number of steps it takes to move all the disks from their initial position to a single stack on another peg without placing a larger disk on top of a smaller one. Only one disk can be moved at any time.

• Given three pegs, one with a set of N disks of increasing size, determine the minimum (optimal) number of steps it takes to move all the disks from their initial position to a single stack on another peg without placing a larger disk on top of a smaller one. Only one disk can be moved at any time.

#### Recursive algorithm:

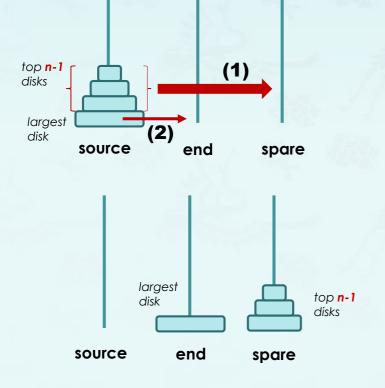

- (1) Move the top n-1 disks from source to spare.
- (2) Move the remaining (largest) disk from source to end.
- (3) Move the n-1 disks from spare to end.

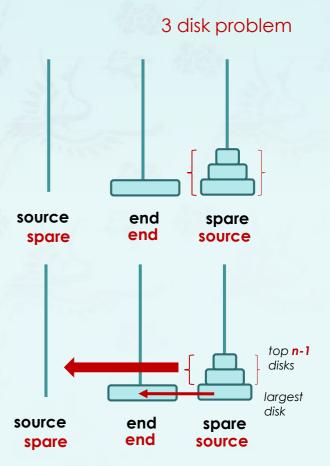

#### Recursive algorithm:

4 disk problem

- (1) Move the top n-1 disks from source to spare.
- (2) Move the remaining (largest) disk from source to end.
- (3) Move the n-1 disks from spare to end.

(3) It becomes a **3 disk problem.**Go back to step 1.
Treat the **spare as source** and the **source as spare**.

#### Recursive algorithm:

- (1) Move the top **n-1** disks from **source** to **spare**.
- (2) Move the remaining (largest) disk from source to end.
- (3) Move the **n-1** disks from **spare** to **end.**

#### How do you program this to have the output as shown below?

```
(1) Disk 1 from A to C
```

- (2) Disk 2 from A to B
- (3) Disk 1 from C to B
- (4) Disk 3 from A to C
- (5) Disk 1 from B to A
- (6) Disk 2 from B to C
- (7) Disk 1 from A to C

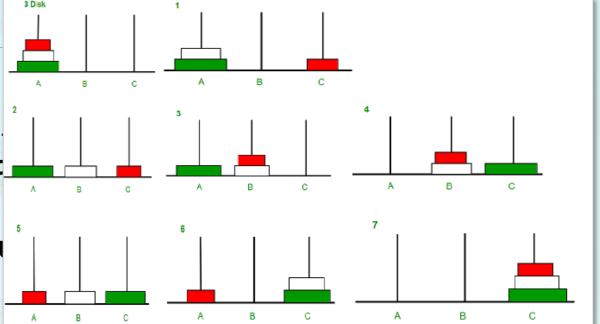

```
void hanoi(int n, char source, char spare, char end) {
  if (n == 1)
    printf("Disk 1 from %c to %c\n", source, end);
  else {
    hanoi(n - 1, source, end, spare);
    printf("Disk %d from %c to %c\n", n, source, end);
    hanoi(n - 1, spare, source, end);
}
```

#### Recursive algorithm:

- (1) Move the top n-1 disks from source to spare.
- (2) Move the remaining (largest) disk from sourc
- (3) Move the n-1 disks from spare to end.

#### How do you program this to have the or

- (1) Disk 1 from A to C
- (2) Disk 2 from A to B
- (3) Disk 1 from C to B
- (4) Disk 3 from A to C
- (5) Disk 1 from B to A
- (6) Disk 2 from B to C
- (7) Disk 1 from A to C

```
void hanoi(int n, char source, char spare, char end) {
  if (n == 1)
    printf("Disk 1 from %c to %c\n", source, end);
  else {
    hanoi(n - 1, source, end, spare);
    printf("Disk %d from %c to %c\n", n, source, end);
    hanoi(n - 1, spare, source, end);
}
```

# Example 6: Time complexity of Tower of Hanoi - O(2<sup>n</sup>)

$$hanoi(n) = \begin{cases} 1 & \text{if } n = 1\\ 2 \cdot hanoi(n-1) + 1 & \text{if } n > 1 \end{cases}$$

Exercise: How many years will it take to move 64 disks while assuming one move per pico second at the clock speed of a super fast machine?

- (1) hanoi(1) = 1
- (2) hanoi(2) = 3
- (3) hanoi(3) = 7
- (4) hanoi(4) = 15
- (5) hanoi(5) = 31
- (6) hanoi(32) = 4,294,967,295
- (7) hanoi(64) = 18,446,744,073,709,600,000

```
hanoi(n = 4)

hanoi(4)

= 2*hanoi(3) + 1

= 2*(2*hanoi(2) + 1) + 1

= 2*(2*(2*hanoi(1) + 1) + 1) + 1

= 2*(2*(2*1 + 1) + 1) + 1

= 2*(2*(3) + 1) + 1

= 2*(7) + 1 = 15
```

#### Recursion

Q: Is the recursive version usually faster?

A: No -- it's usually slower (due to the overhead of maintaining the stack)

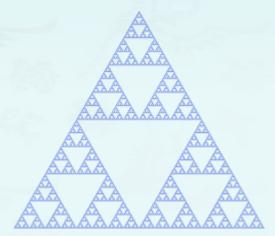

Q: Does the recursive version usually use less memory?

A: No -- it usually uses **more** memory (for the stack).

Q: Then why use recursion?

A: Sometimes it is much simpler to write the recursive version.

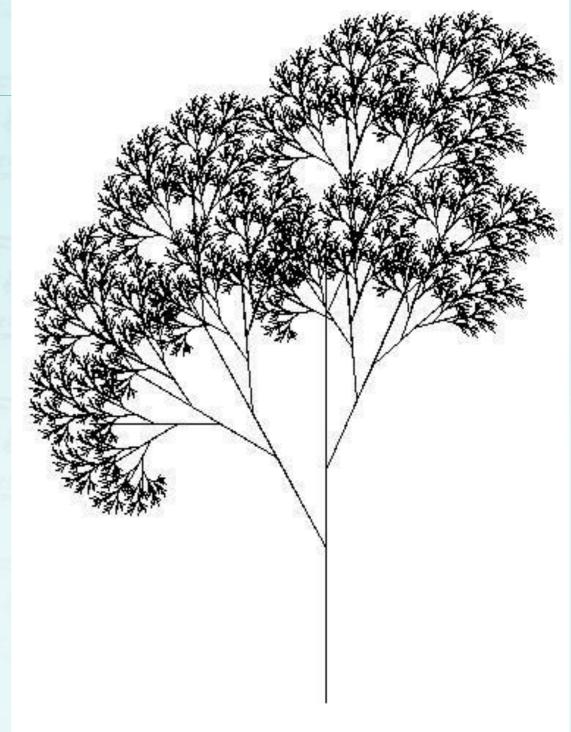

Because the recursive version causes an **activation record** to be pushed onto the system stack for every call, it is also more limited than the iterative version (it will fail, with a "stack overflow" error), for large values of N.

Sierpinski Triangle: a confined recursion of triangles to form a geometric lattice
